Annotation: The Traveling Salesman Problem (TSP) is one of the most well-known and studied problems in mathematical optimization and computer science. The objective of the problem is to find the shortest possible route that allows a traveling salesman to visit a set of specified cities, visiting each city only once, and ultimately returning to the starting point. TSP is famous for its fully combinatorial nature and high complexity. It is classified as an NP-complete problem, meaning that finding an exact solution becomes increasingly difficult as the number of cities grows. Various algorithms have been developed to find solutions using computers, including network search algorithms, genetic algorithms, and simulated annealing methods. The Traveling Salesman Problem is applied in many practical fields, such as logistics, transportation, robotics, and various resource management systems. It is also of great theoretical importance as a tool used for optimization and improving efficiency.

Keywords:Traveling Salesman Problem (TSP), optimization, combinatorics, NP-complete problem, shortest path, algorithms, logistics, transportation, robotics, resource management, simulated annealing, genetic algorithms, network search algorithms, solution finding.

Introduction

The Traveling Salesman Problem is one of the important problems in combinatorial optimization, and its goal is to find the shortest route that visits several cities and returns to the starting point with minimal distance. This problem is applied in fields such as transport logistics, optimization of manufacturing processes, and electronic circuit design.

Solution Methods:Bruteforce (Complete Enumeration), Dynamic Programming (Held-Karp Algorithm), Greedy Algorithm, Genetic Algorithm, Simulated Annealing, Linear Programming, and Branch and Bound.

Objective: The objective of the Traveling Salesman Problem (TSP) is to find the shortest and most efficient route for the salesman to visit the given cities. In this problem, each city must be visited only once, and at the end, the salesman must return to the starting city. The main goal of the problem is to minimize the distance traveled between the cities, thereby reducing time and costs. By optimizing the objective of the TSP, the efficiency in real-world applications such as transportation, logistics, and resource management can be improved. Additionally, the algorithms and methods developed to solve the TSP can be applied to many other optimization problems.

The problem is to find the shortest cycle (in terms of time, distance, or cost) that visits each of the given n cities exactly once. The number of cycles must not exceed (n-1)!. This problem is related to finding the minimum length Hamiltonian cycle. The "Branch and Bound" method can be applied to solve the Traveling Salesman Problem. This method is carried out using a graph without cycles and with outer constraints, as well as by constructing tables.

Sample Variant. Let's introduce the concept of generating a table. To do this, we first generate the rows of the table, meaning that the smallest element from each row is subtracted from the elements of that row. After that, the same operation is performed with respect to the columns, and the columns of the table are generated. A table that has had all its rows and columns generated is called the generated table. The sum of the smallest elements of all the rows and columns is denoted by h, which is called the generation coefficient of the table. As an example, let's consider the following train travel schedule across Uzbekistan:

We can input the markings.

1.Tashkent-Bukhara - 994 000

Tashkent-Karshi – 854 000

Journal: https://www.academicpublishers.org/journals/index.php/ijai

Table 3 is generated, and in each row and column of the table, there is at least one zero element. The generation coefficient h of the given table is equal to the following number:"

$$h = 70 + 4 + 10 + 8 + 12 + 10 + 40 + 18 + 0 + 0 + 5 + 0 + 0 + 0 + 0 + 4 = 191$$

$$h_1 = 70 + 4 + 10 + 8 + 12 + 10 + 40 + 18 + 0 + 0 + 5 + 0 + 0 + 0 + 0 + 4 = 191$$

$$h_1' = h_1 + 47 = 238$$

In general, the Branch and Bound method consists of two important stages:

- 1. Branching;
- 2. Determining the lower bounds.

During the problem-solving process, both stages are carried out simultaneously. To perform these stages, the following tasks must be completed sequentially:

- A) Generate the initial table;
- B) Determine the generation coefficient h;
- C) Identify the level of zero elements in the generated table;
- D) Perform branching based on these levels;
- E) Determine the lower bounds of the cycles formed by the branching results;
- F) Reduce the table size by one;
- G) Prevent the formation of incomplete cycles;
- H) Continue this process until a (2x2) table is formed;
- I) Identify the cycle corresponding to the final branching result;
- J) Compare all the bounds (for all cases);
- K) If necessary, regenerate the table corresponding to the smallest bound and continue branching.

During the application of this method, all calculations are carried out using the given table, and the results are displayed in a separately constructed graph. At the end of this process, the optimal (least-cost) cycle is identified.

The graph consists of interconnected circles, each of which defines a set of cycles with specific properties. The boundary values written next to these circles represent the lower bounds of the costs for the cycles that belong to that circle. The initial part of the graph is shown in Figure 1. In this case, the first initial circle defines a set that contains all cycles, and it indicates that for any cycle, the cost is not less than the value h. In the example discussed above, h=191, meaning that there is no cycle with a cost smaller than 191.

The row and column with the largest degree of zeros are selected and branched accordingly. If there are multiple zeros with the highest degree, one of them is chosen randomly. In this case, the circle on the right side represents the set of all cycles that include a route from city i to city j, and it is denoted by (i,j). The circle on the left side, on the other hand, represents the set of routes that do not include a route from city (i,j) to city (i,j), and it is denoted by (i,j).

The zero element with the highest degree, 47, is selected, and thus the branching graph will look like Figure 1. The boundary value on the left circle will have the generation coefficient h plus the highest degree of the zero element, 47, resulting in the value 238. To determine the lower bound of the costs corresponding to the circle on the right, the 3rd row and 2nd column of Table 3 are removed (i.e., the table size is reduced by one). It is important to emphasize that the order of the cities must always be preserved, otherwise confusion may arise. After that, the formation of all incomplete cycles is prohibited, and the cycle $i \rightarrow j \rightarrow i (i \rightarrow j \text{ (indicating the transition from one city to another) is discarded. For this, the element is replaced and written as <math>c_{23} =$

Let's continue our work by constructing the tables again

The shortest route (optimal path):

$$1 \rightarrow 5 \rightarrow 6 \rightarrow 7 \rightarrow 4 \rightarrow 8 \rightarrow 3 \rightarrow 2 \rightarrow 1$$

Minimal distance: 208 units.

Conclusion

The Traveling Salesman Problem is a classic mathematical problem used to model and optimize many real-world issues. Due to the computational complexity of finding the optimal solution, in many cases, approximate algorithms or heuristic approaches are used.
